Abstract

In situ mass spectrometry has been a powerful tool in many space missions to investigate atmospheres and exospheres of different bodies in the solar system. Applying new technologies the mass spectrometers have become increasingly more sensitive. In this paper we show that spacecraft outgassing, which can never be completely prevented, will be the limiting factor in future missions that investigate very tenuous atmospheres and exospheres of moons, asteroids or comets at large heliocentric distances. The ROSINA (Rosetta Orbiter Spectrometer for Ion and Neutral Analysis) instrument on the ESA Rosetta mission has monitored spacecraft outgassing for 6 years during the cruise phase with unprecedented instrument sensitivity. It is shown that diffusion of gas from materials and from the spacecraft interior plays an important role in maintaining a relatively permanent thin gas cloud around the spacecraft for many years. The density and composition of this gas cloud depends on location on the spacecraft, maneuvers, and payload activity. The main contaminants are water, which is adsorbed on cold surfaces, and organics from the spacecraft structure, electronics and insulations. Decomposed lubricant material can give a significant contribution to the total background. Fortunately for Rosetta, outgassing of the spacecraft will play a minor role when the comet is close to perihelion; only in the early phase of the mission the outgassing may be larger than the cometary signature.
1. Introduction

The contamination of a spacecraft in space by its own outgassing has been a point of concern for some time. It is well known that critical optical surfaces including mirrors, windows, thermal control surfaces and solar cells are susceptible to contaminants like organic materials and water. Therefore, materials used in spacecraft are tested and carefully selected for their outgassing behavior. Contamination control is a key issue in building scientific spacecraft. Nevertheless, it is well known from different spacecraft that, after some time in space, optical surfaces acquire a layer of contaminants which can be significant and which can degrade instrument performance. For example, a gradual deterioration in performance has been reported for the Solar EUV Monitor SEM of the Charge, Element, and Isotope Analysis System CELIAS on SOHO. This performance degradation is consistent with an exponential deposition of 15 nm of carbon over 1300 days (McMullin et al., 2002), which corresponds to a permanent mean particle density of organics around the spacecraft of $\sim5 \cdot 10^4$ cm$^{-3}$. This deposition is non-volatile. For the same spacecraft, the deposition of an ice layer was determined from deterioration of the Extreme Ultraviolet Imaging Telescope performance. The thickness of this layer reaches up to 70 Å per month (Defise et al., 1997). In five years a deposition up to 420 nm is possible. Assuming water is dominant, this corresponds to a mean permanent water molecule density of $\sim5 \cdot 10^5$ cm$^{-3}$ or a partial pressure of $\sim10^{-11}$ mbar (with an assumed temperature of 150 K). This ice layer can be removed by heating the camera or by turning the surface with the deposition into the Sun.

Several missions, e.g. Stardust (Bhaskaran et al., 2004), Cassini-Huygens (Gerhard et al., 2006), Chandra X-Ray Observatory (Plucinsky et al., 2003) and others experienced
unexpected deterioration of their camera systems. All of these missions underwent very rigorous contamination control programs during the fabrication, integration and test up to launch. In most cases contamination could be removed in flight by carefully heating the subsystems, sometimes over very long times. An extensive database of different contamination measurements is given by Green (2001).

Outgassing leads to different problems for scientific in situ mass spectrometers than those experienced by optical systems: Although instrument performance is not affected as such, a limit of detectability for atmospheric neutral and charged particles is given by the gaseous spacecraft environment. For example, the lunar orbital mass spectrometer experiment in the Apollo 15 orbital science package suffered severely from spacecraft outgassing despite being mounted on a boom 7.3 m away from the spacecraft main body (Hoffman et al., 1972).

The impact of contamination by the spacecraft environment is particularly important for any mission trying to analyze thin atmospheres of comets, asteroids or moons, which are at large heliocentric distance or have little volatile material.

Thus far the gaseous environment of a spacecraft has been monitored mostly by using Quartz Crystal Monitors (QCM’s) that accumulate organic material preferentially (e.g. Wood et al., 1997 or Brinza et al., 2000). The only long-term observation of the gaseous and particle environment of a spacecraft, where the density and the composition of the neutral gas and the particle impacts have been monitored, is the Midcourse Space Experiment (MSX) (Uy et al., 2003). The spacecraft was launched in 1996 into an orbit of 900 km from the Earth. This spacecraft was carefully designed with respect to cleanliness considerations because it carried sensitive optical instruments. However, the total pressure sensor as well as the neutral mass spectrometer on MSX reported significant outgassing even after seven years in space. In particular, water, which initially decreased, was still present well above its expected level.
Water vapor measurements showed pressure peaks during spacecraft slews and payload activity. The authors suggested that water is easily adsorbed in multilayer insulation (MLI) and that this insulation represents a large reservoir for outgassing of water.

Cassini-Huygens also has a mass spectrometer for thermal neutral and ionized gas, the INMS (Waite et al., 2004). No measurable spacecraft outgassing was reported by INMS although the camera system on the same spacecraft suffered severely from deposits due to outgassing (Gerhard et al., 2006). The limit of detection of the INMS at $2 \cdot 10^5 \text{ cm}^{-3}$ (Waite et al., 2004) or about $5 \cdot 10^{-12} \text{ mbar}$ (with a temperature of 150 K) for this open ionization source, sets an upper limit on Cassini spacecraft outgassing. In contrast to the camera, where contamination was detected quite early in the mission, the INMS acquired mass spectra only upon arrival at Titan, after about 7 years of interplanetary cruise.

We report here results from the cruise phase of the Rosetta mission of the European Space Agency (ESA) to comet 67P/Churyumov-Gerasimenko (Glassmeier et al., 2007). Rosetta was launched in March 2004 and will encounter its target comet in 2014. In order to match the orbit of the comet, three Earth flybys and a Mars flyby were performed. The minimum heliocentric distance was reached in 2004 at 0.883 AU; the farthest distance thus far was in early 2009 at 2.2 AU. Rosetta encountered the asteroid Steins in September 2008 at a flyby distance of 800 km, had its third Earth flyby in November 2009, and is currently on its way to its 5 AU aphelion. It will approach the comet in 2014 at a heliocentric distance of about 4 AU. At this distance outgassing from the comet is expected to be weak (Schulz et al., 2004) and therefore outgassing of the spacecraft may well be the limiting factor in detecting cometary material.

Rosetta has two mass spectrometers, ROSINA-DFMS (Double Focusing Mass Spectrometer) and ROSINA-RTOF (Reflectron type Time Of Flight mass spectrometer), and a pressure...
sensor ROSINA-COPS (COmet Pressure Sensor) (Balsiger et al., 2007) on board which measure neutral and ionized volatile material in the cometary coma. Both mass spectrometers have unprecedented sensitivity, which allows measurement of very low neutral particle densities. The Rosetta spacecraft will remain in close proximity to the comet for an extended period of time and the relative velocity of the cometary coma and spacecraft will be close to zero. Under these conditions, the two populations, outgassing material from the spacecraft and cometary atmosphere and ionosphere cannot be discriminated by their energy. It is therefore very important to know spacecraft backgrounds before arriving at the comet.

In the present paper we discuss outgassing of the spacecraft as a function of time since launch, heliocentric distance, spacecraft manoeuvres, and payload activity.

2. **Spacecraft and instruments**

A sketch of the spacecraft is given in Fig. 1. Rosetta is approximately a cube with sides of 2.0 x 2.1 x 2.8 m³ and has 64 m² (2m x 16 m on each side of the spacecraft) solar cells mounted on booms extending from the cube. Rosetta was designed to be a very clean spacecraft, not only because of its mass spectrometers, but also because of its optical instruments (e.g. UV spectrometer and optical camera). Outgassing requirements were very stringent for the spacecraft as well as for the payload. MLI is completely sealed on all panels, except the –z panel, where the spacecraft is vented. The spacecraft has thrusters on all eight corners and on the –z panel. All thrusters are shielded from direct view of the payload, which is located mostly on the +z panel. Normal attitude control is done with reaction wheels. Thrusters are used to offload the wheels approximately once per week. On the +y and –y panels there are louvers to control temperature. The high gain antenna is attached to the +x panel and is made of a carbon fibre sandwich structure (Pereira, 2001). The lander (PHILAE) is attached to the –
x panel which also contains cold surfaces for cooling the infrared spectrometer VIRTIS (Coradini et al., 2007). The lander panel is normally kept out of direct sunlight. The solar aspect angle (SAA), defined as the angle between Spacecraft-Sun vector and S/C +z axis, is almost always within ± 5° of the normal to the solar cells. In the x-z plane the SAA varies normally between +15° and +175° from the +z-axis. Far from the Sun, the angle can be larger than 180° for a limited time period, thus illuminating the –x (lander) panel. The positions of the two mass spectrometers and of the pressure sensor COPS are also shown in Fig. 1. In this paper, we present data from all three ROSINA sensors. The main field of view (20°x20°) of DFMS is in the +z direction. In addition DFMS has an opening with a field of view (5°x5°) in the +x direction. The field of view of RTOF is 10° x 40° in the direction of +z. The fields of view of both mass spectrometers exclude any direct line of sight to parts of the spacecraft. The field of view of the COPS nude gauge is almost 4π, and the field of view of the COPS ram gauge is 2π centered on the +z-axis. The nude gauge is mounted on a boom so that it will be in the free flowing neutral gas from the comet.

COPS measures total neutral density with the nude gauge and ram pressure with the ram gauge. The values are converted onboard with a reference temperature of 20°C into pressure. Lower limits are 10^{-11} mbar for the nude gauge and 10^{-9} mbar for the ram gauge. These lower limits are set by electrometer sensitivities. DFMS is a double focusing mass spectrometer with high mass resolution (m/Δm ~ 9000 at FWHM) and sensitivity of 0.5 mbar^{-1}. RTOF is a time-of-flight mass spectrometer covering a large mass range. DFMS and RTOF were built to stringent ultrahigh vacuum specifications and were launched under vacuum. Their vacuum tight covers were released approximately 2 months after launch. Their ion sources were baked up to 300°C in flight. DFMS and COPS have been operated several days per year since shortly after launch whereas, due to outgassing in the high voltage electronics RTOF was not operated
between 2005 and February 2010 and is currently operated with reduced high voltages on the ion optical elements, resulting in somewhat lower sensitivity.

3. **Pressure dependence on elapsed time and heliocentric distance**

The COPS nude gauge, which is located on a boom extending about 25 cm from the instrument platform edge (in Y direction), measures total particle density. It was first turned on 20 days after launch and has been operated regularly since then. The COPS pressure as a function of elapsed time since launch is shown in Fig. 2a. The first pressure reading, 20 days after launch and after allowing for the nude gauge to outgas was at $2 \cdot 10^{-9}$ mbar, rapidly decreasing in subsequent months to $2.5 \cdot 10^{-10}$ mbar. After about 100 days after launch, the slope of the log of the pressure versus time changes noticeably (see Fig. 2a). Around 1100 days after launch, the COPS pressure measurements are close to the detection limit and therefore show large error bars. At that time we can deduce the pressure from DFMS, which is far more sensitive, and find it identical to the COPS pressure within the measurement errors.

During the first 100 days, Rosetta flew within 1 AU from the Sun. One year after launch, Rosetta’s first Earth’s gravity assist occurred. The second Earth’s gravity assist took place approximately 1000 days after launch. Between these two periods, the heliocentric distance of Rosetta increased to 1.8 AU. In September 2008, Rosetta was even further away from the Sun, i.e. 2.2 AU (compare Fig. 2b). However, pressure depends very little on heliocentric distance of the Rosetta spacecraft. Tribble (2000) showed that three different mechanisms are responsible for the outgassing process. They all have different time dependencies and need different activation energies. The processes all follow the relation $e^{\frac{E_a}{RT}}$ with $E_a$ being the characteristic activation energy, $R$ the gas constant and $T$ the temperature. The lowest activation energy is needed by desorption from the surfaces of the spacecraft (4-40 kJ/mole
(Tribble, 2000)). This corresponds to a 1/e temperature range \( T = E_a / R \) of \( 500-5000 \) K depending on the material. Desorption has an exponential dependence on time and it also depends strongly on the temperature of the surfaces. This first mechanism is responsible for pressure profile measured by COPS during the first 200 days after launch. This profile has a 1/e decay time of 30 d (see dotted line in Fig. 2). Rosetta was at a nearly constant heliocentric distance of about 1 AU during this first period. Therefore, its surface temperature was relatively constant and temperature dependence of desorption is not evident in the data.

The second outgassing mechanism is diffusion. Gas from the spacecraft interior and from within the material diffuses slowly to the outside with a time dependence of \( t^{-0.5} \) (see dash-dotted line in Fig. 2a). The mean activation energy for diffusion is higher (20-60 kJ/mole (Tribble, 2000)) than that for desorption. As a result, the 1/e temperature range is \( 2500-7500 \) K. Although the heliocentric distance of Rosetta changed by a factor >2, the surface temperature changed by not more than 50 K and the interior temperature changed by not more than 20 K. Thus, for Rosetta, temperature has little influence on the diffusion process. The third mechanism arises from decomposition of material and is almost time independent (see dashed line in Fig. 2a). The activation energy is high (80-320 kJ/mole). This activation energy can be supplied by, e.g., solar UV, at least for Sun-exposed outer layers of the spacecraft.

Measurements from the COPS pressure sensor and densities derived from DFMS can be very well understood by a combination of these three outgassing mechanisms (see Fig. 2). The contribution of decomposition to total outgassing is negligible for the first 1000 days after launch and still less than 50% after 2000 days after launch. Extrapolating the curve to 4000 days after launch, when Rosetta will be at the comet, the pressure will be still above \( 10^{-11} \) mbar and will be still governed by diffusion.
Pressure history of weekly recorded measurements of the TPS instrument on the MSX mission (Uy et al., 2003) also showed expected exponential decay during the first months of mission lifetime, presumably due to desorption of mainly water. Comparing TPS measurements with the Rosetta data (Fig. 3), the time constants of exponential decay for both instruments within the first 100 days are very similar. Deduced 1/e decay times are 30.7 days for the TPS instrument and 30.1 days for the COPS instrument, respectively, resulting in a nearly parallel slope of both data sets. This is not surprising as both spacecraft were at 1 AU heliocentric distance and desorption dominated early in the missions.

4. **Composition of the gas cloud around the spacecraft**

DFMS is operated in low and high resolution modes, covering a mass range between 12 amu and > 100 amu. A low resolution spectrum taken in March 2010 at 1.7 AU is shown in Fig. 4. The inset shows part of the mass spectrum on a linear scale. The particle density given on the y-axis has to be interpreted with caution, taking into account the uncertainty of the calibration. Different detector yields and ionization cross sections have not been taken into account fully. The error may be as much as a factor of 5. As can easily be seen in Fig. 4, there is a signal for almost every integer mass number.

In the DFMS spectra the dominant mass is water (at 18 amu/e) with a density of about $5 \times 10^5$ cm$^{-3}$ (T=150 K). There is a rich variety of organic compounds present with densities $\leq 10^4$ cm$^{-3}$. This compares well with estimates from the SOHO spacecraft for water (Defise et al., 1997) and for organic compounds (McMullin et al., 2002).

In high resolution mode, parent molecules and fragments can be identified. Figure 5 shows DFMS high resolution spectra as examples for two masslines. From the high resolution spectra...
over the full mass range (12-130 amu/e) we derived all the species and fragments compiled in Table 1.

In the RTOF spectra the dominant mass is fluorine (at mass 19 amu/e) with a density of about \(2 \cdot 10^6\) cm\(^{-3}\); water is about the same as in the DFMS spectra. Again, we find a variety of organic compounds in the spectra. The H and H\(_2\) lines are mostly fragments of the hydrocarbon compounds, but also from the parent molecule of the fluorine.

It is evident that hydrocarbons are abundant. In addition, many nitrogen bearing molecules are found, some of them with oxygen complexes. Also halogen and sulfur containing compounds are identified.

**Hydrocarbon compounds:** Hydrocarbon molecules and polycyclic-aromatic hydrocarbon (PAH) molecules have been identified in ROSINA mass spectra. Possible sources for hydrocarbons are of course polycarbonates (from the spacecraft structure) and solvents. Toluene, Xylene and other solvents or fragments thereof have been identified.

**Nitrogen bearing compounds:** Among them are the parent and fragments of Monomethylhydrazine, the propellant of the Rosetta spacecraft. However, the amount and distribution of these nitrogen bearing fragments suggest other sources which are probably much stronger than thruster fuels. Common spacecraft contamination sources are polyurethane (structure, conformal coatings, and adhesives), epoxies (structure, potting, conformal coatings), polyamines (structure), and polyimides (structure) (Tribble, 2000).

**Halogen and sulfur bearing molecules:** Fluorine is often observed in mass spectrometers with filament ionization sources, e.g. for the mass spectrometer for the Pioneer Venus mission (McFadden et al., 2007). Possible sources for fluorine are remnants from brazing, fluorocarbons contained in the structure, in tapes and in lubricants. DFMS and RTOF both showed traces of fluorine prior to launch. On the contrary, chlorine and sulfur were not
detected prior to launch; however, they may have many sources because they are known contaminants in a lot of processes and are also contained in some solvents. Heating the DFMS ion source for several days at 300 °C in flight did neither change the amount of gas measured nor its composition. That means, except part of the fluorine, that recorded chemicals are not from the DFMS ion source but are from the gas cloud around the Rosetta spacecraft.

**Lubricant:** A comparison between a RTOF mass spectrum and a low resolution DFMS spectrum, both taken in March 2010 reveals significant differences (see Fig. 6). For DFMS the highest peak is clearly water at mass/charge 18 amu/e followed by mass 28 (CO / N₂) and mass 44 (CO₂). For RTOF the highest peak is fluorine, which is more than a factor of 10 larger than the water peak. Apart from this peak, mass 15 (CH₃, NH), the group around mass 28 with significant peaks at 27 and 29 and the group around mass 40 with significant peaks at 39, 41 and 43 are prominent whereas water and CO₂ are rather minor. The pattern in the RTOF spectrum around mass 28 and 40 amu/e is very typical for aliphatic (C-C bonds) compounds. Interestingly, Marshall et al. (2003) deduced the same pattern with the Advanced CCD Imaging Spectrometer (ACIS) on the Chandra X-ray mission. The authors analyzed the contaminant of this instrument by the X-ray absorption edges and determined the composition of the contaminant to be >80% carbon, 7% oxygen and 7% fluorine. They concluded that there are no C=C bonds and no C-F bonds, but that the contaminant has to be an aliphatic fluorine containing molecule. These facts point to the lubricant (Braycote vacuum grease) for the source of the contamination in the case of ACIS / Chandra. This lubricant is used in different mechanisms of Chandra. Braycote is a perfluorated polyester that can be damaged by radiation (UV, X-ray) and be converted into an aliphatic compound. The high gain antenna of Rosetta uses the same lubricant. The antenna is attached to the +x-panel (see Fig. 1). The +x-panel is
normally in sunlight, which may lead to relatively high temperatures and to a degradation of the lubricant. The difference between RTOF and DFMS can be explained by their different locations on the spacecraft. The RTOF ion source is on the same panel as the high gain antenna and not too far away. The view direction is the same as for DFMS in the direction of +z. DFMS is on the +z-panel together with the rest of the payload. Although there is no direct line of sight between the entrance of the RTOF ion sources and the high gain antenna mechanisms, gas can much more easily be scattered into the RTOF ion sources than into the DFMS ion source. Still some of the degraded lubricant also reaches the entrance of DFMS as can be seen by the fluorine peak. We can therefore confirm the findings of the ACIS / Chandra contamination investigation that the lubricant Braycote forms aliphatic compounds under radiation which are more volatile than the original molecules.

5. Variability of Background

During the past year, a set of data was acquired by ROSINA, indicating that the background as discussed in section 4 is not constant with time, not even on a short timescale. We find that several operational effects are influencing instrument contamination and background in the mass spectrometers must be taken into account.

5.1. Spacecraft attitude

Since instruments are in general fixed with respect to the spacecraft coordinate system, the spacecraft has to change attitude in order to insure an optimal view direction for the payload. Optimizing the orientation results in changing illumination conditions of countless parts of a spacecraft, in particular exposing panels to sunlight that have been in shadow earlier, and vice versa. This effect was already reported by Uy et al. (2003) for the Midcourse Space
Experiment (MSX) satellite. We demonstrate that this effect constrains scientific measurements at larger heliocentric distances.

5.1.1. Asteroid Steins flyby

The effect of spacecraft attitude on the ROSINA instrument background was recognized during ESA’s first asteroid flyby in September 2008: Rosetta approached its target, the E-type asteroid (2867) Steins, with a relative velocity of 8.6 km/s to approximately 800 km closest approach (CA) on 5 September 2008 18:38:20 UTC. The flyby took place at a heliocentric distance of 2.1 AU.

Two spacecraft maneuvers were performed during the flyby. From 17:58 to 18:18 UTC Rosetta rotated around its z-axis (see Fig. 1) in order to prevent illumination of thermally sensitive parts, which would have limited observations after closest approach (CA). The second maneuver was a slew started shortly before CA in order to keep the z-axis (bore sight of instrument platform) pointing to the asteroid and allow continuous observation by remote sensing instruments.

Planned ROSINA measurements during the Steins-Flyby were intended to contribute to exploration of the asteroid’s environment, in particular to search for a low level gaseous envelope (Schläppi et al., 2008). The flyby strategy was to use COPS to monitor total neutral particle density while DFMS would monitor a narrow mass range. DFMS focused on a limited mass range in order to avoid time consuming adjustments of the ion optical potentials and thus risk missing interesting data during the short flyby. Since (2867) Steins is a thermally evolved object, the monitored mass was set to detect sputtered oxygen from the asteroid’s surface; the monitored mass to charge ratio was set to m/q=15.5 amu/e, which allows simultaneous detection of several species: O, CH$_4$, NH$_2$ as well as CH$_3$ and NH.
ROSINA results from the Steins flyby are presented in Fig. 7. This figure clearly shows a correlation between spacecraft attitude and instrument background. This led to our hypothesis that illumination of cold panels exposed to sunlight after years in darkness causes evaporation of gases condensed on these panels.

One of the peculiarities that attract attention in Fig. 7 is the time delay of signal variations observed between DFMS and COPS. The spatial separation of the sensors of about 1 m and typical velocities of thermally released particles (a few times 100 m/s) are certainly not the reason for the observed time delay of a few minutes. To explain this delay, one needs to consider different fields of view (FOV) of the two sensors (see Fig. 1). It is therefore reasonable to assume that certain outbursts from the spacecraft are observed by COPS, but not by DFMS. However, the first peak observed by DFMS is also observed in COPS data with a partial pressure of approximately $10^{-10}$ mbar. This is evident in the slope of the exponential decay around 18:17 UTC, which changes due to the outburst observed by DFMS.

We exclude the possibility that the observed variations are due to internal instrument outgassing since during the first DFMS pressure peak (maximum at ~18:20 UTC), the ion source was not illuminated at all and the temperature increase observed is negligible (from -26.8°C at 18:00 UTC to -25.6°C at 18:20 UTC). Furthermore the ion source was baked out at 300°C for almost 2 days preceding these measurements.

### 5.1.2. Compositional measurements during spacecraft thermal characterization tests

Based on results from the Steins flyby, the European Space Operation Control team provided ROSINA with an additional opportunity to investigate the observed behavior: During a spacecraft thermal characterization test conducted 16-18 February 2009, ROSINA was able to perform extended compositional measurements of the spacecraft desorption behavior.
Characterization tests consisted of several test periods at different orientations. On 16 February 2009 at 14:00 UTC Rosetta was slewed from its “nominal” attitude, with Solar Aspect Angle (SAA) ~72°, to SAA =175°. During the entire test period, the S/C y-axis was perpendicular to the Rosetta-Sun axis. Rosetta remained at this orientation for 24 hours and was then slewed by 17°. With SAA = 192° the spacecraft -x panel was slightly illuminated. After another 24h Rosetta returned to the initial orientation of SAA=72°. The maneuvers took place at a heliocentric distance of approximately 2.2 AU. Figure 8 depicts total pressure during the characterization as measured by the COPS nude gauge. Obviously, during every maneuver, COPS observes pressure peaks, corresponding to release of volatiles from the spacecraft. Surprisingly, adjacent to the slew on 17 February, 14:00 UTC, the pressure remains at least an order of magnitude higher than before the slew (considering the lower detection limit of about $1 \cdot 10^{-11}$ mbar of COPS).

Thermal characterization tests, in particular the maneuvers on 17 February, were used to investigate the composition of the spacecraft outgassing. Several low and high resolution spectra over the full mass range of DFMS (m/q=12-140 amu/e) were taken before and after the slew. During the manoeuvre the same mode as during the Steins-flyby was used. Figure 9 shows that water clearly dominates the released gas, but small amounts of CH$_4$ and CO$_2$ might be present.

With current instrument sensitivities, we estimate that the partial H$_2$O pressure increased from approximately $2.3 \cdot 10^{-11}$ mbar (approximate particle density: $1.1 \cdot 10^6$ cm$^{-3}$) at 12:30 UTC to $6.1 \cdot 10^{-11}$ mbar ($2.9 \cdot 10^6$ cm$^{-3}$) at 14:45 while the partial CO$_2$ pressure was $3.8 \cdot 10^{-12}$ mbar ($1.8 \cdot 10^5$ cm$^3$) before and $4.7 \cdot 10^{-12}$ mbar ($2.3 \cdot 10^5$ cm$^3$) after the slew. COPS observed an increase of the total pressure by a factor 10, in contrast to DFMS, where only the partial water pressure was increased by a factor of approximately 3. The observed difference might be a
superposition of the already described field of view effect and the proximity of the sensors with respect to the source of the released gas. Furthermore, derived partial pressures suffer from large uncertainties (approximately 50%) since DFMS is still not optimized and no extensive, quantitative calibration has been performed for water yet. Despite these uncertainties, results indicate a significant water reservoir, possibly carried along with Rosetta since launch in 2004 and replenished by combustion of monomethylhydrazine during thruster firings, which yields H$_2$O and CO$_2$ (de Bonn et al., 2001).

5.2. Payload operations

In most cases space probes carry a set of different instruments, each contributing to the main scientific goals of the mission. It is clear, that during periods where science data are recorded, several instruments operate simultaneously and therefore dissipate energy and warm up. As they warm, they contribute to background gas. This effect was observed by COPS several times when the GIADA instrument (Grain impact Analyser and Dust Accumulator (Colangeli et al., 2007)) was operated simultaneously. COPS registered an increased background pressure (approximately factor 4) during these interference tests. However, this increase is not surprising since GIADA is one of the closest instruments to COPS. More staggering are measurement performed during a Rosetta payload checkout in September 2009, where several interference tests or combined measurements with other payload instruments have been performed in conjunction with DFMS operation.

Figure 10 shows results of an interference test with the ROSETTA Lander PHILAE (Bibring et al., 2007) as well as an attempt to combine measurements with Ptolemy, a GCMS sensor on board the Lander (Wright et al., 2007). Both units are mounted on the spacecraft –x panel and are therefore clearly outside the DFMS FOV. During the Lander interference test, a clear increase in H$_2$O and CO$_2$ signals was observed by DFMS as soon as the Lander was operated.
Another interference test was planned with Ptolemy. The plan was to cross calibrate the two mass spectrometers (DFMS and Ptolemy). Unfortunately these measurements could not be conducted because Ptolemy suffered an unexpected anomaly. But, as Fig. 10 shows, DFMS detects an increase in the partial pressure of water as soon as Ptolemy was switched on. During both interference tests, the spacecraft attitude remained constant, no ROSINA instrument anomalies occurred and no variations of sensor temperatures could explain the increase in partial pressures. The results of these tests provide strong indication that instrument operations must be considered to assess variability of the background.

5.3. Thruster operations

It has been shown elsewhere that thruster operations can lead to a large increase in pressure around the spacecraft (Graf et al., 2007). While pressure increases due to thruster operation can be even harmful for instruments, (mainly increasing the danger of discharge for instruments using high voltages) the pressure after a thruster firing decreases relatively rapidly within minutes to acceptable levels for payload integrity. There remains, however, a higher pressure for tens of minutes after the thruster firing at the position of the COPS nude pressure sensor despite the shielding of the direct line of sight between COPS and all thrusters. Figure 11 shows the total pressure for more than 3 days starting before and proceeding through the Steins flyby. There are several large pressure peaks. Peaks labeled with TF1, TF2, and TF3 are due to thruster firing of various thrusters. The peak which is not labeled is due to the spacecraft flip of almost 180° around the y-axis.

Figure 12 shows details of the third thruster firing (TF3). There is clearly a fast drop of the pressure after, in this case, multiple thruster firings, but there remains an elevated pressure of about $2 \times 10^{-11}$ mbar for more than an hour. This elevated pressure may be due to hydrazine
droplets evaporating slowly from the thruster nozzles (not very likely due to the shielding of the thrusters) or to evaporation of thruster firing products deposited on different spacecraft surfaces during thruster operation.

6. **Origin of the gas cloud around spacecraft**

The observed deterioration of optical surfaces and the non-internal neutral background measured with mass spectrometers presented in this paper require consideration of a redistribution of the contamination onboard a spacecraft, likely caused by a significant return flux of released material.

For satellites in geosynchronous Earth orbit, Thomas et al. (1998) note that the main return flux mechanism for neutral particles is molecular backscattering caused by collisions among released material. Robertson (1976) presented a simple model to estimate the relative return flow rate of outgassing products due to collisions among outgassing molecules (self-scattering) and collisions among outgassing and ambient molecules (ambient-scattering).

Using this model and results from the MRMU (Molecular Return Measurement Unit) experiment onboard the Atmosphere Explorer D satellite, Scialdone et al. (1978) estimated that at altitudes of 300-350 km self-scattering becomes the major contribution to the return flow in the Earth atmosphere. Ambient scattering is negligible for deep space missions and we therefore use the self-scattering model of Robertson (1976) to estimate the release rate necessary to backscatter enough material to explain the measurements of the DFMS sensor:

For a spherical spacecraft of radius $R$ with isotropic outgassing, the return flow fraction $\Phi_b/\Phi_r$, with $\Phi_b$ the backscattered and $\Phi_r$ the released flux (in units molecules m$^{-2}$s$^{-1}$), can be calculated from the following expression (derived from Robertson, 1976):
Where $m$ is the mass, $\sigma$ is the collisional cross section of the released particles and $k$ is the Boltzmann constant. Using the observed particle number density ($10^{11}$ m$^{-3}$) and an assumed particle velocity of 500 m/s, we derive a backscatter flux of $\Phi_b = 5 \cdot 10^{13}$ m$^{-2}$s$^{-1}$ entering the ion source of the DFMS or RTOF instrument. Solving the above equation for the release rate with parameters of H$_2$O molecules ($m=18$ amu, $\sigma=2.5 \cdot 10^{-19}$ m$^2$), a spherical spacecraft with radius $R=1.5$ m and a wall temperature of $T=300$ K, results in a (physical meaningful) water loss rate of about $1.9 \cdot 10^{18}$ molecules m$^{-2}$s$^{-1}$ for the spherical spacecraft, which seems quite reasonable. This water loss rate corresponds to the release of 0.2 monolayers per second or to about 1.8 kgm$^{-2}$yr$^{-1}$ for the spherical spacecraft. Contrary to this model, a real spacecraft is considerably more complex. The main part of the observed particle densities probably arises through direct flow and (multiple) scattering of contaminants on spacecraft parts. Therefore, we expect a significant lower release rate per unit area than obtained from the sphere model.

However, the total release rate of molecules of Rosetta is of the order of several hundred grams per year. Rosetta has a dry mass of 1180 kg. We assume that 30% of Rosetta consists of non-metallic material (epoxy, carbon fiber structure, multilayer blankets, electronics, insulated wiring, etc.). This spacecraft material has been selected for its low outgassing, defined by its total mass loss of less than 1% at 125°C in 24h in vacuum (Campbell and Scialdone, 1993). The characteristic time constant for outgassing due to diffusion is indirectly proportional to the diffusion coefficient and therefore follows the relation $e^{E_a/RT}$ (compare to
Chapter 3 for the notation). Hence, with a generic activation energy of $E_a=50\text{kJ/mol}$, timescales for outgassing at a temperature of $0\,^\circ\text{C}$ (which is approximately what we expect for a spacecraft) is about a factor $10^3$ larger compared to the specifications at $125\,^\circ\text{C}$. A material meeting the outgassing specification will therefore suffer approximately the same total mass loss during 1000 d in flight as during the outgassing tests. Considering the limit of 1% total mass loss during test periods, we conservatively estimate an average lifetime loss rate of 0.5%. The estimated non-metallic material onboard Rosetta would therefore loose about 2 kg or more during its 10 year mission duration. Additionally, all surfaces carry adsorbed material (water). An estimation of the corresponding active area is difficult, especially since certain spacecraft materials have significantly larger effective surfaces than geometric area (e.g. MLI or honeycomb structures). If we account only for the central box of Rosetta with a total surface of $31\,\text{m}^2$ and the solar panels with a surface of $64\,\text{m}^2$ (which are made from honeycomb structure), we get an effective surface area of about $5000\,\text{m}^2$. The total surface area of Rosetta may well be up to $10000\,\text{m}^2$. Adsorbed water on aluminum surfaces of the honeycomb structure is on the order of $10^{21}$ molecules $\text{m}^{-2}$ (Chen et al., 2001) which yields several hundred grams of water eventually diffusing to the outside. The reservoir for outgassing of water and organic compounds is therefore quite large and can easily explain observed densities.

7. **Conclusions**

The most important process of outgassing during the first 200 days of a mission is desorption of water from exposed surfaces of the spacecraft. The half-life of the density associated with desorption is approximately 21 days for a spacecraft at 1 AU. Prolonged outgassing due to diffusion leads to a gas cloud around the spacecraft with a density of approximately $10^5\,\text{cm}^{-3}$.
once the desorption process has cleaned the surfaces. Decomposition of the material starts to play a role for long missions after several years in space. Decomposition is mostly due to solar UV radiation which delivers enough activation energy for this process.

While the background may vary somewhat from spacecraft to spacecraft there is quite a good correspondence between our measurements and those of the MSX and SOHO spacecraft. The partial water pressure is in the low $10^{-11}$ mbar range and appears to be almost generic for all spacecraft; the partial pressure for organic material (H, C, N, and O bearing molecules) is one order of magnitude lower.

Backscattered material from spacecraft parts or from self-scattering is deposited preferentially on cold panels of a spacecraft, leading to a large reservoir of volatile material. Unfortunately the background is not a constant but depends on many parameters like spacecraft attitude, payload and subsystem operation, etc. Even the composition of the background is not uniform around the spacecraft. Shadowed parts contain mostly water, whereas parts that are mostly in the Sun show a large contribution from decomposition (e.g. lubricants). This may explain that the contamination of sensitive surfaces varies quite a lot from spacecraft to spacecraft and between instruments on the same spacecraft. We can confirm that the contaminant due to the lubricant Braycote is an aliphatic compound containing a lot of fluorine as was detected by ACIS /Chandra (Marshall et al., 2004).

This gaseous background clearly interferes with detection by in situ mass spectrometry of weak signals from atmospheres and exospheres of small bodies or bodies with little outgassing, There is no easy solution, as long as the relative spacecraft velocity is small. All scientific spacecraft undergo a stringent contamination control. As long as a spacecraft carries MLI’s, honeycomb structures, electronics, payload, insulated wires, etc. it will outgas water and organic material. Once immersed in the atmosphere or exosphere to be investigated there
is almost no way to separate static background from signal. Each spacecraft attitude change may change the background; even closing of a cover may change the local background for a highly sensitive mass spectrometer like DFMS.

There are a few measures that can be taken to mitigate the problem. By modeling outgassing of a spacecraft, there may be the possibility to find a “good” position on the spacecraft for a mass spectrometer, a position where outgassing is minimal. By taking into account the small bulk velocity of the gas to be measured there is the possibility to apply very small retarding potentials just after the ionization section of the instrument in order to discriminate background. Because the ionization process also influences the energy of the ions this may not be feasible for bulk velocities below 1 km/s or for the light masses (H, H₂, He, C, etc.). It could also be foreseen to use a very small shutter mechanism a short distance in front of the mass spectrometer entrance. Background may be determined by measuring in a quasi phase locked loop with and without shutter. All of these measures could reduce the background problem somewhat, but not by many orders of magnitude. Thus, due to the presence of the spacecraft, enhanced sensitivities of mass spectrometers will not necessarily lead to lower detection limits for atmospheres and exospheres.

For the ROSINA instruments, these findings are crucial for future operations during the second half of the mission: In July 2010 Rosetta will fly by the asteroid (21) Lutetia, where ROSINA will be used to investigate whether this body exhibits some low level activity (Schläppi et al., 2008). It is planed to perform a flyby-rehearsal in order to identify possible spacecraft outbursts at given attitudes. Comparison of the rehearsal and the flyby data should allow us to derive a sensitive upper limit of Lutetia’s outgassing rate.

During early comet operations at a heliocentric distance > 3 AU in 2014, ROSINA data analysis will have to be done with extreme caution to distinguish “false comet signals” arising
from spacecraft outgassing from the real cometary signature. To quantify these interferences, an isotropic radial outflow model for the comet without sources or sinks was calculated for three different cases (Table 2).

With these parameters, it is expected that ROSINA will be able to identify major cometary species (H₂O, CO or CO₂) at large heliocentric distances > 3 AU. However, as Figure 13 clearly demonstrates, in order to detect minor species, such as HCN or CH₄, specific measurement methods will be necessary at 3 AU. At 1.3 AU, close to perihelion, the interference will be negligible.

Acknowledgements

The authors would like to thank the following institutions and agencies, which supported this work: Work at UoB was funded by the State of Bern, the Swiss National Science Foundation and by the European Space Agency PRODEX Program. Work at BIRA-IASB was supported by the Belgian Science Policy Office via PRODEX/ROSINA PEA 90020. Research at Lockheed Martin Advanced Technology Center and work at the University of Michigan were supported under JPL subcontract 1266313 under NASA prime contract NMO710889. The work on ROSINA in France was supported by CNES through grants CNES/ROSETTA/98-70 to 04-70. We would also like to thank the Flight Operations group at ESOC which provided us with the opportunities to study the outgassing behavior of Rosetta during special tests.

**Figure captions**

Fig. 1: Rosetta spacecraft with the three ROSINA sensors (COPS, DFMS and RTOF). The +z-panel (instrument panel) is on top in this picture. The lander is on the –x panel. The solar aspect angle is measured between the Spacecraft-Sun vector and +z-axis. In almost all cases the solar aspect angle between the y- and x-axis is 90° (perpendicular to the solar cells).

Fig. 2: Panel a: COPS and DFMS pressure data as a function of time t since launch. The dotted line shows the outgassing due to desorption $p_d \propto e^{-t/t_d}$ with $t_d = 30$ d. The dashed-dotted line is the outgassing due to diffusion $p_{dif} \propto \frac{1}{\sqrt{t}}$ and the dashed line shows the contribution from decomposition ($p_{dc} = const$). The solid line represents the sum of the three contributions and has been fitted with the free parameters ($t_d$, $p_d$, $p_{dc}$, $p_{dif}$) to the data. Error bars of COPS measurements are uncertainties of digitalization while error bars of DFMS measurements are due to ion statistics. Panel b gives the heliocentric distance of Rosetta as a function of time since launch.

Fig 3: A comparison of the pressure data from the TPS sensor on the MSX spacecraft (Uy et al., 2003) and ROSINA-COPS on Rosetta for the first 100 days of the mission. Lines are exponential fits to the data. The TPS sensor was about a factor of 20 less sensitive than the COPS sensor. Therefore, the data stop at $2 \times 10^{-10}$ mbar, which was reached after 40 days. The pressure on Rosetta is about a factor of 5 larger, probably due to the much bigger size of the spacecraft. The 1/e decay time of desorption ($t_{1/e} = 30$ days), however is almost identical for the two spacecraft.
Fig 4: DFMS mass spectrum in low resolution of 14 March 2010, at a heliocentric distance of 1.7 AU. Integration time per mass line is 20 s and electron emission current 200 μA. The inset shows part of the mass spectrum in a linear scale to illustrate the mass resolution in this low resolution mode.

Fig. 5: Two DFMS high resolution spectra, integration time 20s, electron emission current 200 μA.

Fig. 6: Comparison of a low-mass section of mass spectra from DFMS and RTOF taken in March 2010. The RTOF peak at mass 19 is fluorine which is partly from an internal source. The acquisition time of DFMS for the total spectrum was 20 minutes compared to 3 minutes for RTOF and the DFMS electron emission was higher by a factor of 2 which accounts partly for the higher DFMS sensitivity.

Fig. 7: ROSINA Steins flyby results from COPS and DFMS. Panel a: 2 peaks were observed in the DFMS Oxygen-intensity. One clearly correlated with the S/C flip, the other one appeared around CA (indicated by bold line). Panel b: COPS nude gauge pressure with a sharp edge when the flip was started (17:58 UTC). Note the change in the slope around 18:17 UTC. Variations are also apparent around CA. Panel c: Rosetta spacecraft orientation according to SPICE (Acton, 1996).
Fig 8: Solar aspect angle and COPS nude gauge pressure during the thermal characterization test of Rosetta in February 2009. The first peak observed by COPS is due to internal outgassing, but an overlapping peak is visible when SAA was approximately 90°.

Fig 9: DFMS composition measurements during the slew of 17 Feb. 2009. Several low (LR) and high resolution (HR) spectra were obtained before and after the maneuver, the intensities have been normalized to the last spectrum obtained before 13:45 UTC. The red line indicates the slew. From approx. 11:25 to 11:52 UTC DFMS was set to standby in order to prevent potential software complications. This explains the small peak at ~12:00 UTC, when the filament was heated again and some outgassing from the filament occurred. Error bars from ion statistics were only drawn for high resolution spectra, for others they are negligible. The instrument performance was without any problems and DFMS was in shadow during the whole maneuver. We therefore exclude outgassing of the sensor itself and conclude that the observed outburst was a result of the illumination condition.

Fig. 10: Results from interference tests between ROSINA and the Lander Philae (upper panel) and Ptolemy (lower panel). The thick line indicates the switch on of the corresponding unit. The flank of the signal at the beginning of each measurement is due to DFMS outgassing of the filament.
Fig. 11: Total pressure measured by COPS during the asteroid Steins flyby. The peaks denoted by TF1, TF2 and TF3 are all coincident with thruster firings. The peak at 60 hours after start of the measurement is due to a spacecraft flip of $180^\circ$ around the y-axis.

Fig. 12: Pressure during and after thruster firing. Multiple thrusters have been activated in this case which yields pressure peaks of almost 3 orders of magnitude above the background level. The pressure decreases at the end of the firing within minutes to the $10^{-11}$ mbar range, but stays above the background level (dashed line) for more than an hour.

Fig. 13: Comparison of ROSINA DFMS background and expected particle densities at Rosetta’s final target 67P/Churyumov-Gerasimenko at 30 km distance. Gas velocity was assumed to be 300 m/s. Grey bars are the average of the CO$_2$ and H$_2$O driven early comet activity models (3 AU heliocentric distance). Errors depict the variations between the two models. The background may be somewhat lower for the 3 AU case due to the larger heliocentric distance.
