ABSTRACT
As the spin axis of comet 67P/Churyumov–Gerasimenko (67P) is not normal to the orbital plane, 67P has strong seasonal changes in the illumination conditions on the nucleus’ surface, with a short and intense summer in the Southern hemisphere. We have been monitoring these seasonal variations in the gas coma with the Rosetta Orbiter Spectrometer for Ion and Neutral Analysis (ROSINA) instrument suite aboard the ESA’s Rosetta spacecraft. Rosetta followed 67P from its rendezvous in 2014 August, from a distance of almost 3.5 au to Sun, through perihelion at 1.24 au, and away from Sun again. In this study, we present the change of outgassing pattern during the 2016 March equinox based on measurements acquired with the ROSINA instruments: while H2O, O2 and NH3 abundances rapidly decreased during this period, CO2, CO, H2S, CH4 and HCN abundances decreased much less and showed a strong south–north heterogeneity for the whole period, thus not following Sun. Sublimation temperatures of the pure ices are found to be uncorrelated with the slope of the decrease for the minor species. This can be interpreted as a consequence of two different ice phases, water ice and CO2 ice, in which the minor species are embedded in different relative abundances.

Key words: comets: individual: 67P/Churyumov–Gerasimenko.

1 INTRODUCTION
Comet 67P/Churyumov–Gerasimenko (hereafter 67P) was accompanied by the European Space Agency’s Rosetta spacecraft for more than 2 yr along its trajectory around Sun. During this period, the comet crossed equinox for the first time in 2015 May, passed perihelion in 2015 August, and the second equinox in 2016 March, a few months before the mission was concluded with a final descent on the nucleus of the comet. On board was ROSINA, the Rosetta Orbiter Spectrometer for Ion and Neutral Analysis instrument suite, built to monitor composition and abundance of the volatiles in the coma of the comet (Balsiger et al. 2007). ROSINA consisted of a pressure sensor and two complementary mass spectrometers, which together were well suited for this task.

67P has a changing rotation period (Keller et al. 2015) around a rotation axis tilted with respect to the orbit plane (Sierks et al. 2015). Hence, the illumination conditions on the nucleus surface are constantly changing in direction as well as in intensity given the variation in heliocentric distance from perihelion at 1.24 au to

★ E-mail: sebastien.gasc@space.unibe.ch
aphelion at 5.68 au. Summer on the Southern hemisphere is short and intense; summer on the Northern hemisphere is the opposite. This leads to strong seasonal heterogeneities of the volatiles in the coma, which was already observed early in the mission (Hässig et al. 2015; Le Roy et al. 2015). Given the strong asymmetries observed from north to south, it becomes especially interesting to track some of the major volatiles across equinox, when both hemispheres change season. The comet has been shown to be quite heterogeneous in its morphological features on the surface (Thomas et al. 2015; El-Maarry et al. 2016). However, deriving internal structure from clathrates (Prialnik, Benkhoff & Podolak 2004; Marboeuf & Schmitt 2014; Lectez et al. 2015; Rubin et al. 2015; Mousis et al. 2016). One of the main goals of the Rosetta mission was hence to study the development of cometary activity and the processes in the surface layer of the nucleus (Glassmeier et al. 2007). The rapid changes in the illumination conditions over a moderately short-time period during the outbound equinox in 2016 March – when Rosetta spent time close to the nucleus – and associated variations in the distributions of the volatiles in the coma can add crucial information to the understanding of a comet’s activity. The measurements obtained by ROSINA provide boundary conditions for deriving surface outgassing (Fougere et al. 2016; Marschall et al. 2016) and outgassing properties derived from numerical models of the nucleus interior and corresponding ices (Davidsson & Gutierrez 2005; Rosenberg & Prialnik 2009; Marboeuf & Schmitt 2014). Section 2 of this paper presents a short description of the ROSINA instrument suite, followed by the details of the data treatment of the pressure sensor and both mass spectrometers. The obtained measurements are shown in Section 3 and our conclusions follow in Section 4.

2 MATERIALS AND METHODS

2.1 Instrument descriptions

ROSINA consists of the Comet Pressure Sensor (COPS) and two mass spectrometers, the Double Focusing Mass Spectrometer (DFMS) and the reflectron-type time-of-flight (RTOF) mass spectrometer. The three instruments work together to provide absolute density measurements of the major and minor volatiles in the coma of 67P.

In this study, we use data from all three instruments. It is therefore important to keep in mind that they all detect volatile neutral species, but that there are some important differences on how they measure. All three sensors ionize neutral particles by electron impact. However, their electron energies are different: 70, 45 and 0–150 eV for RTOF, DFMS and COPS, respectively. Whereas COPS measures the total neutral density every 2 s, but transmits data in a normal mode only every minute, RTOF collects one spectrum in 100 µs, but then accumulates 2 million spectra before the accumulated spectrum is transmitted. DFMS has to measure at integer mass numbers sequentially with an integration time of 20 s which yields 50 min for a full spectrum, including overhead for voltage stepping.

While COPS measures the combined density of all the species and does not separate masses, RTOF has a mass resolution $m/\Delta m \approx 500$ and a mass range in the mode used for these measurements from 1 to 120 u, and DFMS has a mass resolution of $m/\Delta m \approx 9000$ (at FWHM and mass 28 u) covering mostly masses from 13 to 100 u. RTOF is operated in a counting mode, while DFMS measures in an analogue mode the charge deposited from the MCP on to the anode. COPS measures directly the ion current. Sensitivity for RTOF and COPS depends mainly on the ionization cross-section of the different species, while DFMS has a mass-sensitive transmission and adjustable detector gain, which has to be taken into account. For more details, the reader is referred to Balsiger et al. (2007) and Scherer et al. (2006).

2.2 Data treatment

The RTOF data in this study were acquired with the storage source, designed to study neutrals (Balsiger et al. 2007). The data reduction is similar to that described in Gasc et al. (2017) and consists of (i) the correction of the ADC pattern for each spectrum individually, (ii) the application of the mass scale for each spectrum, (iii) the fitting and the numerical integration of each peak of interest, here H$_2$O and CO$_2$, and (iv) the scaling of the RTOF relative densities to the COPS measured absolute density values. Additionally, the first 30 min after each spacecraft manoeuvre has been systematically removed to minimize the impact of the outgassing of the ion source following the switch ON and heating up of RTOF.

The DFMS data in this study were acquired in a high-resolution mode (Balsiger et al. 2007). The data reduction process is the same as presented in Le Roy et al. (2015) and Calmonte et al. (2016) and consists of (i) MCP-related intensity correction, (ii) a mass calibration, (iii) the determination of the peak area per spectrum and per species and (iv) the conversion to number density for each species. For (iii), an automatic analysis software described in Calmonte et al. (2016) has been used to determine the peak area corresponding to CH$_4$, NH$_3$, H$_2$O, HCN, CO, O$_2$, H$_2$S and CO$_2$. The well-known contribution of CO from fragmentation of CO$_2$ has been subtracted from the CO signal to leave only cometary parent CO. The conversion to density (iv) is based on scaling the DFMS relative abundances measurements to the measured COPS total density shown in Fig. 1 as described in Gasc et al. (2017).

2.3 Observation period

The measurements discussed in the following were obtained with ROSINA during the extension of the Rosetta mission between 2016 January 1 and August 1, i.e. at heliocentric distances increasing from 2.0 to 3.5 au. The total density derived from the COPS measurements as well as some relevant orbital parameters of 67P and Rosetta during this time period are given in Fig. 1.

The chosen time frame covers the outbound equinox that occurred on 2016 March 21 at a heliocentric distance of 2.63 au. Coincidently, this distance matches the water iceline (or water condensation front), located around 2.7 au (Jewitt et al. 2007). During the studied period, the mean cometary activity decreased with distance as expected compared to perihelion, allowing the Rosetta spacecraft to get closer to the nucleus, from 90 to 7 km from the comet centre. Unfortunately, no ROSINA data are available for the interval 2016 March 23–2016 April 27 due to a tail excursion that brought Rosetta to a distance of 1000 km from the nucleus. Apart from this excursion, Rosetta remained mostly in a terminator orbit and studied the nucleus of 67P with a nadir off-pointing most of the time smaller than 10$^\circ$. In particular, fast slewings and large off-pointing angles can lead to increased release of volatiles trapped

The time evolutions of the H$_2$O and CO$_2$ densities measured by RTOF are presented in Fig. 2 and cover the time period from 2016 January to June. After 2016 June, the RTOF observation times were reduced due to power limitations.

Two different trends can be observed in the RTOF data. On the one hand, CO$_2$ abundance decreases relatively slowly as a function of the comet’s distance from the Sun, while showing large variations with changing sub-spacecraft latitude. On the other hand, H$_2$O shows small variations with sub-spacecraft latitude but a significant decrease with the increasing heliocentric distance, correlated with the sub-solar latitude.

The anticorrelation of CO$_2$ with the sub-spacecraft latitude already observed by RTOF before perihelion (Mall et al. 2016) was still clearly visible after perihelion, independent of the outbound equinox. On a shorter time-scale, the high-time resolution of RTOF (200 s) translates to a high-spatial resolution in the CO$_2$ time series, where diurnal variations are as well still visible and similar to measurements earlier in the mission (see Fig. 3).

To a lesser extent, the RTOF H$_2$O measurements show the anticorrelation with the sub-spacecraft latitude observed after the inbound equinox; before the inbound equinox, water molecules were emanating more abundantly from the Northern hemisphere, which was translated into a clear correlation with the latitude (Hoang et al. 2017). The sub-solar latitude changed slowly reaching about 16° north by the end of July. This is clearly different from the situation we had at the beginning of the mission in 2014 September when Sun was almost at 50° north for the same heliocentric distances. Accordingly, while the heterogeneity for water between north and south did change after equinox, it did not reach the situation where much more water was released from the Northern hemisphere than from the south as in 2014 September (Hässig et al. 2015). The pattern we see is rather flat, indicating that water is following the
Figure 2. Top panel: evolution of H$_2$O (blue) and CO$_2$ (red) densities measured by RTOF between 2016 January and June, corresponding to a heliocentric distance ranging from 2.0 to 3.1 au. The densities derived from the RTOF measurements have been multiplied by $r^2$, with $r$ the distance from the Rosetta spacecraft to the centre of the comet, to compensate for the decrease of the atmospheric density which follows a $r^{-2}$ law. Bottom panel: sub-solar latitude (dashed red) and sub-spacecraft latitude (black).

sub-solar latitude to the equator and then beyond. This can be seen if looking carefully at Fig. 3, where water actually peaks around 0° latitude in 2016 May.

### 3.2 DFMS

The time evolutions of the densities measured by DFMS for CH$_4$, NH$_3$, H$_2$O, HCN, CO, O$_2$, H$_2$S and CO$_2$ are shown in Fig. 4. The DFMS data from 2016 May (heliocentric distance from 2.91 to 3.12 au) are not shown due to the small amount of data points for the studied species in this period. DFMS confirms the global trend observed with RTOF for H$_2$O and CO$_2$ and allows distinction of two populations: species such as H$_2$O, O$_2$ and NH$_3$ show less difference in their north/south abundances than CO$_2$, CO, H$_2$S, CH$_4$ and HCN, which stay high over southern latitudes and are significantly lower at northern latitudes. These two populations are in agreement with the results shown by Luspay-Kuti et al. (2015), except for HCN, which in 2014 showed a significantly better correlation with H$_2$O than with CO$_2$. To quantify the different behaviour, we have fitted the data for latitudes $>30^\circ$ (north) and $<-30^\circ$ (south) with a power law to the heliocentric distances. The power-law indices $\alpha$ are given in Table 2 and the corresponding plots can be found in the Appendix. No correlation of the power-law indices $\alpha$ with the sublimation temperature of pure ices is observed (see Fig. 5). We have also calculated the mean ratio $R_{SN}$ between south and north abundances for 2016 March and July. The generally steeper decrease with heliocentric distance in the south compared to north is most probably an effect of the change in sub-solar latitude: more northern parts and less southern parts are illuminated with time and therefore with heliocentric distance. Accordingly, the ratios between south and north are smaller in 2016 May than in 2016 March.

The strong heterogeneity of the coma can be mostly explained by solar insolation. In addition, however, some inhomogeneity of the nucleus surface has to be taken into account (Fougere et al. 2016), which is mostly attributed to dust coverage in the north and fresher material in the south. Fig. 6 illustrates the changes in abundance with the sub-spacecraft latitude for 2016 March. No difference between...
measurements acquired at dawn (local time close to 6:00) and at dusk (local time close to 18:00) can be observed. During and after the outbound equinox, the variations between the two hemispheres of H$_2$O, together with O$_2$ and NH$_3$, are much weaker than before the outbound equinox, but the long-term trend reveals a considerable decrease in the water sublimation. This decrease is due mostly to the increasing heliocentric distance, as the period around equinox coincided with the crossing of the snow line of water.

O$_2$ was known to follow H$_2$O in the coma of comet 67P/Churyumov–Gerasimenko before the inbound equinox with ratios of 0.01–0.1 compared with H$_2$O and a mean O$_2$/H$_2$O ratio from 2014 September to 2015 April of 0.0380 ± 0.0085 (Bieler et al. 2015a). After the outbound equinox, these ratios remained similar (see Table 1), with a temporal evolution of O$_2$ following closely the evolution of H$_2$O. Fig. 7 shows correlation plots for all species with respect to H$_2$O and CO$_2$ for two periods, near and post equinox (2.4–2.7 and 3.2–3.5 au, respectively). The O$_2$–H$_2$O correlation is clear for both periods. On the short term H$_2$O and NH$_3$ correlate well, but on the long term, between 3.2 and 3.5 au and after the outbound equinox, the evolution of NH$_3$ is flatter with distance to Sun. Most other species show very little correlation with H$_2$O, although some intrinsic correlation is given by the change in heliocentric distance over the periods, which affects all species, but not all alike. CO$_2$ and H$_2$O do not correlate, whereas CO, CH$_4$, HCN and H$_2$S correlate rather well with CO$_2$.

The species varying strongly with the sub-spacecraft latitude during equinox, i.e. CO$_2$, CO, H$_2$S, CH$_4$ and HCN, all had very similar trends, especially before 2016 April and the exchange of seasons between both hemispheres: detected more abundantly in the Southern hemisphere, the outgassing of these molecules decreased slowly and regularly on the long term, following the increasing heliocentric distance and thus the decrease of the solar input. These similarities were observed likely post-equinox, with a slight difference regarding H$_2$S, CH$_4$ and HCN which locally resembled water, around 3.18 au, i.e. with higher abundances at sub-spacecraft latitudes close to 0°.

4 DISCUSSIONS AND CONCLUSIONS

ROSINA, RTOF and DFMS monitored a set of eight molecules, including CH$_4$, NH$_3$, H$_2$O, HCN, CO, O$_2$, H$_2$S and CO$_2$, for several weeks throughout the outbound equinox of comet 67P. Rosetta orbited the comet in the terminator plane and hence covered both hemispheres of the comet repetitively. This provided the unique possibility to compare not only the different outgassing patterns of these molecules but also their temporal variations as the illumination of the nucleus was changing. Strong north/south heterogeneities have been observed, similar to observations early in the mission which were also performed beyond 3 au (Hässig et al. 2015), although in the pre-perihelion period the total outgassing was always dominated by H$_2$O (Fougere et al. 2016). Water seems to follow the sub-solar latitude, which was expected given its rather high sublimation temperature (Hansen et al. 2016). CO$_2$ does not trend the same way, as the Southern hemisphere remained its main source and, hence, towards the end of the mission, the southern, winter hemisphere dominated the outgassing of 67P through CO$_2$.

The general decrease over the period in abundances varies greatly from species to species. It does not follow the sublimation temperatures of pure ices (Table 2). The smallest decrease is seen in CO$_2$, which exhibits at the same time the highest variation between north and south during equinox. The power law with heliocentric distance is roughly −2 for the Southern hemisphere and −0.7 for the northern part. That means the outgassing of CO$_2$ is not an instant response to solar illumination, but rather due to heat diffusion into and thermal inertia of deeper layers below the surface. On the other hand, H$_2$O seems to follow the subsolar latitude. The power law with an exponent of −7 and −11 for north and south, respectively, shows that temperatures of the nucleus are below the sublimation temperature of water on both hemispheres, even at subsolar
67P’s outgassing pattern during equinox

Figure 4. Evolution of the most abundant species detected by DFMS between 2016 January and August, at heliocentric distances ranging from 2.0 to 3.5 au. In the same way as for the RTOF measurements, the DFMS densities have been multiplied by $r^2$, the squared distance from the Rosetta spacecraft to the cometary nucleus. Top panel: H$_2$O, O$_2$ and NH$_3$; CO$_2$ is added in grey for comparison. Middle panel: CO$_2$, CO, H$_2$S, CH$_4$ and HCN; H$_2$O is added in grey for comparison. Bottom panel: sub-spacecraft latitude (black) and sub-solar latitude (red).

latitudes. O$_2$ is a special case. Its exponents of $-6.7$ to $-8.9$ for the power law are close to the water, although its volatility is very high, second only to CO, confirming the close relationship between water and O$_2$ (Bieler et al. 2015a). Molecular oxygen, O$_2$, which, according to Bieler et al. (2015a), hints at formation inside pre-solar water ices by irradiation processes, leads to a close relation between the two molecules (cf. Mousis et al. 2016) despite grossly different sublimation temperatures (see Table 2). If we include earlier findings, e.g. the lack of correlation of molecular nitrogen, N$_2$, with water (Balsiger et al. 2015) and the correlation of O$_2$ with water, we end up with two species, N$_2$ and O$_2$, with almost indistinguishable desorption patterns as a function of temperature (Collings et al. 2004) but vastly different outgassing profiles measured at the comet.

After equinox, CO$_2$ remained dominant in the Southern hemisphere, more abundant than on the better illuminated Northern hemisphere. The same applied to CO, H$_2$S, CH$_4$ and HCN, although some of them with a less strong north/south variation in the measured density. According to Collings et al. (2004), species that are co-deposited with water at cold temperatures, where water is amorphous, desorb in three steps: the first step is close to the
Sublimation temperatures of pure ices, the second step, which is the same for all species more volatile to water, happens at ≈120 K, where water converts from amorphous to crystalline (volcano desorption) and the third step happens at the sublimation temperature of water. The behaviour of the species studied here does not follow this scheme. There are clear differences in desorption patterns between species that cannot be explained by their volatility. For example, CH$_4$ (36 K) and HCN (126 K) have very different sublimation temperatures, but show very similar slopes with heliocentric distances. O$_2$ and CH$_4$ have very similar sublimation temperatures, but have completely different slopes. This cannot be explained by pure ices, but hints at mixtures of species and ice types. The heterogeneity seen in most species between north and south might have their origin in the hemispherical differences between the northern and southern surfaces of the comet. The intense summer in the south sets free fresh material and the outgassing of volatiles continuously sheds any accumulated dust mantle. Kramer et al. (2017) showed that sources of enhanced gas activity were correlated to the location of dust outbursts observed within 3 months around perihelion (2015 July–September). Furthermore, these gas sources remained active until the end of the mission, much longer compared to the dust outbursts that typically last for only a few minutes and dust itself appears to be dry (De Keyser et al. 2017). In the north, lower outgassing rates and back-fall of dust (Agarwal et al. 2016; Keller et al. 2017) possibly quench the outgassing rate. If such grains contain any volatiles such as water, outgassing from back-fall would certainly be dominated by these species. Species of higher volatility would be long lost by the time of redeposition. Therefore, higher relative abundance of water is not in contradiction to the scenario proposed by Keller et al. (2017).

There exist models of desorption from cometary nuclei and laboratory experiments where species more volatile than water desorb and migrate outwards and inwards where they freeze out again (e.g. Meckler, Priailnik & Podolak 1990, and references therein; Notesco & Bar-Nun 2000, and references therein). However, most of the models and all of the experiments take into account much larger relative abundances of the minor species. In our data, relative abundances, except for CO$_2$, were all in the 1 per cent range before and around equinox and therefore very minor. It cannot be expected that pure ices of these minor species exist in the comet. Their sublimation temperature, with the exception of CO$_2$, may therefore be irrelevant because for desorption of a minor species in a matrix of volatiles and dust, van der Waals forces in the host matrix, which are different from the pure ices, are responsible. The continuous strong outgassing from the southern parts over many months and even years with very little water is probably indicative of CO$_2$ ice. CO$_2$ was found to be abundant in the coma over the Southern hemisphere already at the beginning of the Rosetta mission (Häusig et al. 2015) after the southern part had been in shadow for 5 yr. Experimentally, it has been shown by Fayolle et al. (2011) that with an intimate mixture of H$_2$O:CO$_2$ of 5:1, the topmost layer saturates quickly with H$_2$O molecules and the pores become void of more volatile species below the sublimation temperature of H$_2$O and the surface layer is then impenetrable for CO$_2$. This would suppress CO$_2$ outgassing quite rapidly, once the temperature of the surface layer is below the sublimation temperature of water. This clearly does not happen at the comet (Fig. 2). Our conclusion is that the ices cannot be intimately mixed, be it due to primordial separation or by evolution.

Therefore, a possible explanation for the observed sublimation temperature-independent diversity in desorption could be that minor species are partly embedded in CO$_2$ and partly in H$_2$O ices. Their different power laws with heliocentric distance are then indicative for the ratio between how much is embedded in CO$_2$ and are therefore co-desorbed with CO$_2$ and how much is embedded in water and is released by the volcano effect or by sublimation of water. Good examples are H$_2$S and HCN, which generally follow CO$_2$ (power-law indices of $-$1.57 to $-$3.59), but show some signature of the water release not seen in CO$_2$ like the double peak at, e.g. 3.18 au (Fig. 4). This means that the nucleus consists partly of CO$_2$ dominated ices, partly of H$_2$O dominated ones. If this is a primordial heterogeneity or due to differentiation because of

### Table 2. Other properties of the species studied in this work. Sublimation temperatures $T_{\text{sub}}$ are derived from Fray & Schmitt (2009) (sublimation from pure ices). The power-law indices $\alpha$ were calculated for latitudes $> 30^\circ$ (north) and $< -30^\circ$ (south), via a fit of the data with a power law to the heliocentric distances. Mean ratios $R_{S/N}$ between north and south abundances for 2016 March and July are given in the two rightmost columns. Species are sorted according to their slope $\alpha$ – south with heliocentric distance for the Southern hemisphere.

**Figure 5.** Power-law indices $\alpha$ versus sublimation temperature, for the studied species and for latitudes $> 30^\circ$ (north) and $< -30^\circ$ (south). The grey boxes represent the error on $\alpha$. 

![Graph](https://example.com/graph.png)
Figure 6. Evolution of the studied species with respect to the sub-spacecraft latitude for the time period 2016 February 19–2016 March 23 (2.40–2.63 au). Grey points represent measurements acquired at dawn (local time close to 6:00), whereas black points represent measurements acquired at dusk (local time close to 18:00).

Figure 7. Top: scatter plot of CO$_2$ versus H$_2$O. Lower left graphs: scatter plots of the studies species versus H$_2$O. Lower right graphs: scatter plots of the studies species versus CO$_2$. The measurements shown here belong to the time period 2016 February 19–2016 March 23 (2.40–2.63 au, grey), and June 13–August 1 (3.20–3.50 au, black).
evolution is hard to say. There is, however, no indication that polarity of the species plays a role, as one might expect that polar species are more likely to be embedded in water and apolar ones in CO₂. Furthermore, also how each molecule is embedded in the ice, either through trapping, formation in the ice through radiation, grain-surface chemistry or refreezing, affects probably the structure and therefore the van der Waals forces in the matrix and the later desorption. Clearly, more laboratory work on low mixing ratios in H₂O and, in particular, CO₂ ice has to be done.

Before the end of the Rosetta mission, the comet transitioned to be dominated by highly volatiles. Towards outbound equinox in 2016 March at ≈2.6 au, the CO₂ abundance increased with respect to H₂O and, while the turnover was not instant, CO₂ became the dominant molecule in the coma of the comet, at least at the location of Rosetta in the terminator plane. This behaviour is associated with the low sublimation temperature and is in line with what has been observed at other comets, such as CO (possibly with contribution of Rosetta dominant molecule in the coma of the comet, at least at the location of Rosetta in the terminator plane. This behaviour is associated with the low sublimation temperature and is in line with what has been observed at other comets, such as CO (possibly with contribution of Rosetta

**ACKNOWLEDGEMENTS**

The authors thank the following institutions and agencies, which supported this work. Work at the University of Bern was funded by the State of Bern, the Swiss National Science Foundation and the European Space Agency PRODEX (PROgramme de Développement d’EXPériences scientifiques) Program. This work was supported by CNES (Centre National d’Etudes Spatiales) grants at LATMOS (Laboratoire Atmosphères, Milieux, Observations Spatiales) and IRAP (Institut de Recherche en Astrophysique et Planétologie). Work at the University of Michigan was funded by NASA under contract JPL-1266313. Research at Southwest Research Institute is funded by NASA through JPL contract No.196541. Work by JHW at the Southwest Research Institute was funded by NASA JPL subcontract NAS703001T97010889. Work at BIRA-IASB was supported by the Belgian Science Policy Office via PRODEX/ROSETTA PEA90020 and 4000107705 and by the F.R.S.-FNRS grant PDR T.1073.14 ‘Comparative study of atmospheric erosion’. Work at the Max Planck Institute for Solar System Research was funded by the Max-Planck Society and Bundesministerium für Wirtschaft und Energie under contract 50QP1302. ROSINA would not give such outstanding results without the work of the many engineers, technicians and scientists involved in the mission, in the Rosetta spacecraft and in the ROSINA instrument team over the past 20 yr, whose contributions are gratefully acknowledged. Rosetta is an European Space Agency (ESA) mission with contributions from its member states and NASA. We thank herewith the work of the whole ESA Rosetta team. All ROSINA flight data have been released to the PSA archive of ESA and to the PDS archive of NASA.

**APPENDIX: SUPPLEMENTARY MATERIAL**

The densities of the eight studied molecules have been fitted using the non-linear least-squares Marquardt–Levenberg algorithm, for latitudes >30° (north) and <−30° (south), and based on the following power law:

\[ n \cdot r^2 = C \cdot r_h^\alpha \]

with \( n \) the density of the fitted species, \( r \) the distance of the Rosetta spacecraft to the nucleus centre, \( r_h \) the heliocentric distance, \( \alpha \) the fitted power-law indices and \( C \) a constant parameter. The fit was done using logarithmic values to account for the small weight of the low densities on the y-axis:

\[ f_{\text{fit}}(r_h) = \alpha \cdot \log_{10}(r_h) + \log_{10}(C) \]

The data points, their associated fit and the fitted value of \( \alpha \) are shown in Figs A1 and A2.
Figure A1. From top to bottom: densities ($\times r^2$) of CH$_4$, NH$_3$, H$_2$O and HCN, fitted with a power law to the heliocentric distance, for sub-spacecraft latitudes $>30^\circ$ (north – dashed blue) and $\leq -30^\circ$ (south – red).

Figure A2. From top to bottom: densities ($\times r^2$) of CO, O$_2$, H$_2$S and CO$_2$, fitted with a power law to the heliocentric distance, for sub-spacecraft latitudes $>30^\circ$ (north – dashed blue) and $\leq -30^\circ$ (south – red).
